## Model Evaluation

How do we know how good a given

We could evaluate it on the data used to build the model. This would give us insight into how the selected model performs. However, this would only give an estimate of performance on this data. If the data used to build the model was different from the data used to test it, this performance would be biased.

## Why?

It is helpful to take it to an extreme:

**A model that remembered the timestamps and value for each observation would achieve perfect performance.**

All real models we prepare will report a pale version of this result.

When evaluating a model for time series forecasting, we are interested in the performance of the model on data that was not used to train it. In machine learning, we call this unseen or out of sample data.

We can do this by splitting up the data that we do have available. We use some to prepare the model and we hold back some data and ask the model to make predictions for that period. The evaluation of these predictions will provide a good proxy for how the model will perform when we use it operationally.

In applied machine learning, we often split our data into a train and a test set: the training set used to prepare the model and the test set used to evaluate it. We may even use k-fold cross validation that repeats this process by systematically splitting the data into k groups, each given a chance to be a held out model.

**These methods cannot be directly used with time series data.**

This is because they assume that there is no relationship between the observations, that each observation is independent.

This is not true of time series data, that we cannot randomly split them to respect the temporal order in which they occurred.

In time series forecasting, this evaluation is called backtesting. In some time series domains, it is called hindcasting, as opposed to forecasting.

We will look at three different methods for fitting machine learning models on time series problems.

1. **Train-Test split** that respect temporal order of observations.
2. **Multiple Train-Test splits** that respect temporal order of observations.
3. **Walk-Forward Validation** where a model may be updated each time step new data is received.

First, let's take a look at a small, univariate time series data we will use as context to understand these three backtesting methods: the Sunspot dataset.

## Monthly Sunspot Dataset

This dataset describes a monthly count of the number of observed sunspots for just over 230 years (1749-1983).

The units are a count and there are 230 rows of data. The data is credited as Andrews & Herzberg (1985).

- Download the dataset.

Below is a sample of the first 5 rows of the dataset:

```
1 "Month", "Sunspots"  
2 "1749-01", 58.0  
3 "1749-02", 62.6  
4 "1749-03", 70.0  
5 "1749-04", 55.7  
6 "1749-05", 85.0
```

Below is a plot of the entire dataset:

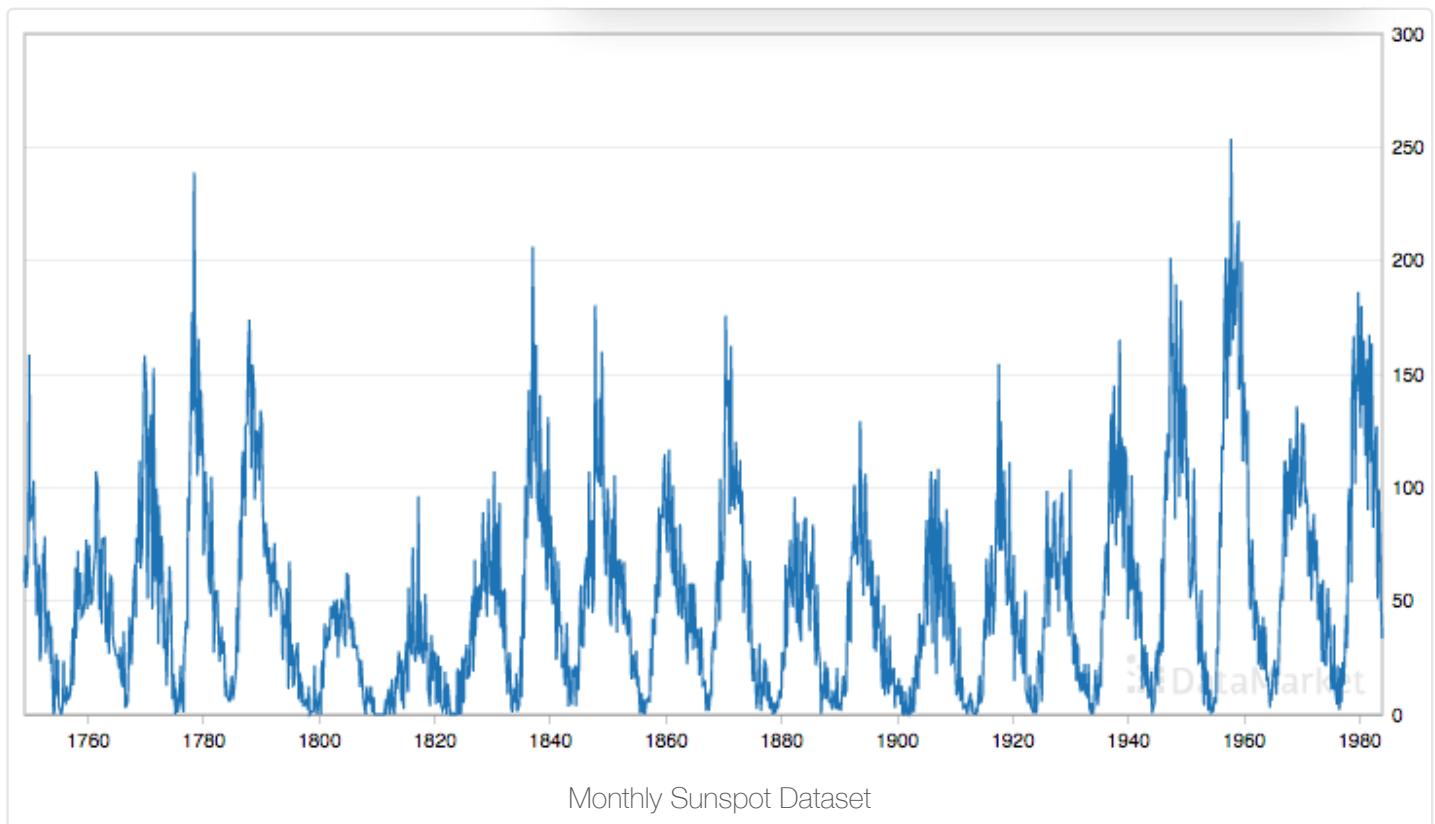

## Your Start in Machine Learning

START MY EMAIL COURSE

It is straightforward to split data in Python.

After loading the dataset as a Pandas Series, we can extract the NumPy array of data values. The split point can be calculated as a specific index in the array. All records up to the split point are taken as the training dataset and all records from the split point to the end of the list of observations are taken as the test set.

Below is an example of this in Python using a split of 66-34.

```
1 from pandas import Series
2 series = Series.from_csv('sunspots.csv', header=0)
3 X = series.values
4 train_size = int(len(X) * 0.66)
5 train, test = X[0:train_size], X[train_size:len(X)]
6 print('Observations: %d' % (len(X)))
7 print('Training Observations: %d' % (len(train)))
8 print('Testing Observations: %d' % (len(test)))
```

Running the example prints the size of the loaded dataset and the size of the train and test sets created from the split.

```
1 Observations: 2820
2 Training Observations: 1861
3 Testing Observations: 959
```

We can make this visually by plotting the training and test sets using different colors.

```
1 from pandas import Series
2 from matplotlib import pyplot
3 series = Series.from_csv('sunspots.csv', header=0)
4 X = series.values
5 train_size = int(len(X) * 0.66)
6 train, test = X[0:train_size], X[train_size:len(X)]
7 print('Observations: %d' % (len(X)))
8 print('Training Observations: %d' % (len(train)))
9 print('Testing Observations: %d' % (len(test)))
10 pyplot.plot(train)
11 pyplot.plot([None for i in test])
12 pyplot.show()
```

Running the example plots the train

Sunspot Dataset Train-Test Split

Using a train-test split method to evaluate machine learning models is fast. Preparing the data is simple and intuitive and only one model is created and evaluated.

It is useful when you have a large amount of data and want a representative of the original problem.

Next, we will look at repeating this process multiple times.

## Multiple Train-Test Splits

We can repeat the process of splitting the data multiple times.

This will require multiple models to be created. The computational expense will provide us with multiple models to evaluate.

## Your Start in Machine Learning

You can master applied Machine Learning without math or fancy degrees. Find out how in this *free* and *practical* course.

[START MY EMAIL COURSE](#)

performance of the chosen method and configuration on unseen data.

We could do this manually by repeating the process described in the previous section with different split points.

Alternately, the scikit-learn library provides this capability for us in the *TimeSeriesSplit* object.

You must specify the number of splits to create and the *TimeSeriesSplit* to return the indexes of the train and test observations for each requested split.

The total number of training and test observations are calculated each split iteration (*i*) as follows:

```
1 training_size = i * n_samples / (n_splits + 1) + n_samples % (n_splits + 1)
2 test_size = n_samples / (n_splits + 1)
```

Where *n\_samples* is the total number of observations and *n\_splits* is the total number of splits.

Let's make this concrete with an example. Assume we have 100 observations and we want to create 2 splits.

For the first split, the train and test sizes would be calculated as:

```
1 train = i * n_samples / (n_splits + 1) + n_samples % (n_splits + 1)
2 train = 1 * 100 / (2 + 1) + 100 % (2 + 1)
3 train = 33.3 or 33
4
5 test = n_samples / (n_splits + 1)
6 test = 100 / (2 + 1)
7 test = 33.3 or 33
```

Or the first 33 records are used for training.

The second split is calculated as follows:

```
1 train = i * n_samples / (n_splits + 1)
2 train = 2 * 100 / (2 + 1) + 100 % (2 + 1)
3 train = 66.6 or 67
4
5 test = n_samples / (n_splits + 1)
6 test = 100 / (2 + 1)
7 test = 33.3 or 33
```

## Your Start in Machine Learning

You can master applied Machine Learning  
**without math or fancy degrees.**  
Find out how in this *free* and *practical* course.

Email Address

START MY EMAIL COURSE

Or, the first 67 records are used for training and the remaining 33 records are used for testing.

You can see that the test size stays consistent. This means that performance statistics calculated on the predictions of each trained model will be consistent and can be combined and compared. It provides an apples-to-apples comparison.

What differs is the number of records used to train the model each split, offering a larger and larger history to work with. This may make an interesting aspect of the analysis of results. Alternately, this too could be controlled by holding the number of observations used to train the model consistent and only using the same number of the most recent (last) observations in the training dataset each split to train the model, 33 in this contrived example.

Let's look at how we can apply the TimeSeriesSplit on our sunspot data.

The dataset has 2,820 observations. Let's create 3 splits for the dataset. Using the same arithmetic above, we would expect the following train and test splits to be created:

- **Split 1:** 705 train, 705 test
- **Split 2:** 1,410 train, 705 test
- **Split 3:** 2,115 train, 705 test

As in the previous example, we will plot the train and test observations using separate colors. In this case, we will have 3 splits, so that will be 3 separate plots of the data.

```
1 from pandas import Series
2 from sklearn.model_selection
3 from matplotlib import pyplot
4 series = Series.from_csv('sunspots.csv')
5 X = series.values
6 splits = TimeSeriesSplit(n_splits=3)
7 pyplot.figure(1)
8 index = 1
9 for train_index, test_index in splits.split(X):
10     train = X[train_index]
11     test = X[test_index]
12     print('Observations: %d' % len(test))
13     print('Training Observations: %d' % len(train))
14     print('Testing Observations: %d' % len(test))
15     pyplot.subplot(310 + index)
16     pyplot.plot(train)
```

## Your Start in Machine Learning

You can master applied Machine Learning without math or fancy degrees.

Find out how in this *free* and *practical* course.

Email Address

START MY EMAIL COURSE

```
17     pyplot.plot([None for i in train] + [x for x in test])
18     index += 1
19 pyplot.show()
```

Running the example prints the number and size of the train and test sets for each split.

We can see the number of observations in each of the train and test sets for each split match the expectations calculated using the simple arithmetic above.

```
1 Observations: 1410
2 Training Observations: 705
3 Testing Observations: 705
4 Observations: 2115
5 Training Observations: 1410
6 Testing Observations: 705
7 Observations: 2820
8 Training Observations: 2115
9 Testing Observations: 705
```

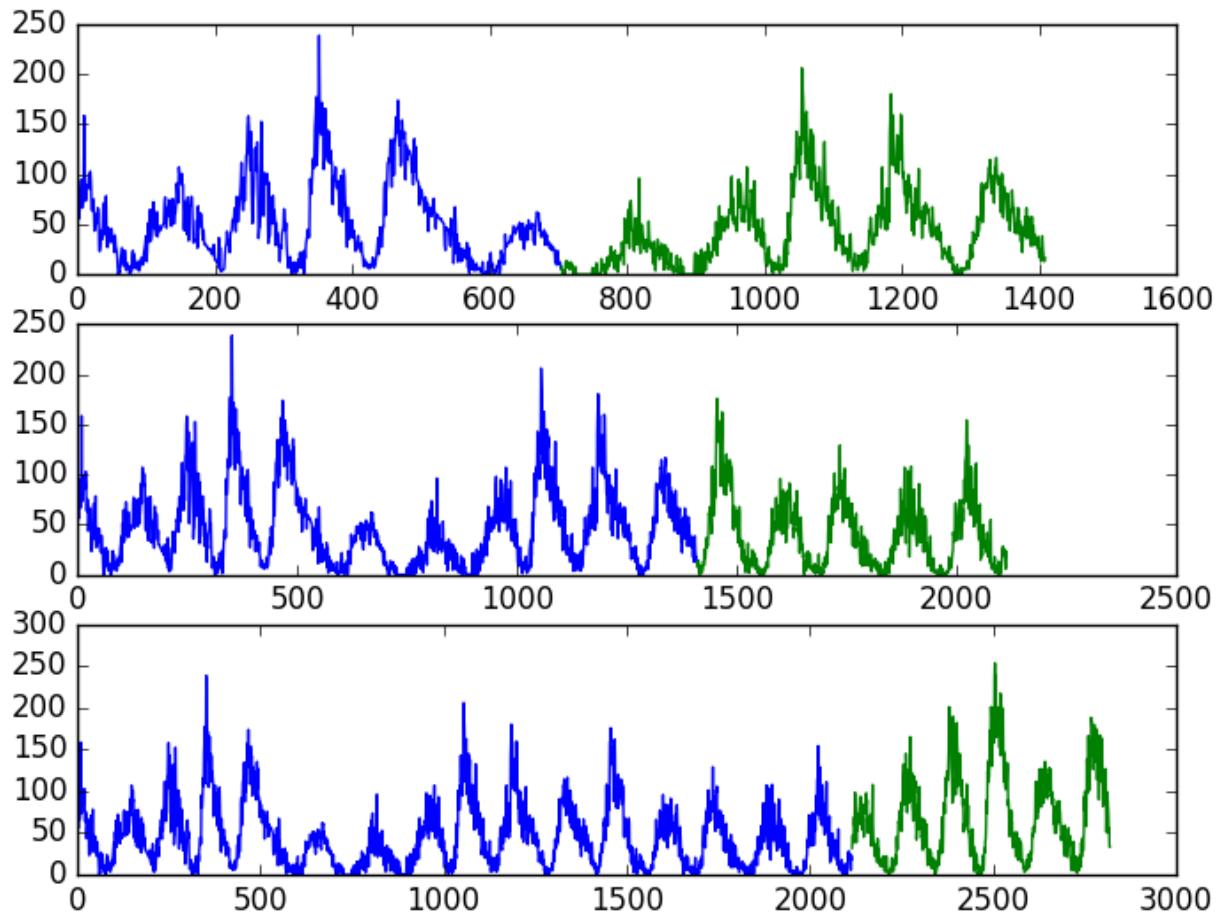

The plot also shows the 3 splits and the growing number of total observations in each subsequent plot.

Sunspot Dataset Multiple Train-Test Split

Using multiple train-test splits will result in more models being trained, and in turn, a more accurate estimate of the performance of the models on unseen data.

A limitation of the train-test split approach is that the models are only evaluated on each evaluation set once it is available.

This may not be realistic as models are often retrained on all available observations as new data is made available. This is called

## Walk Forward Validation

In practice, we very likely will retrain our model on all available data at each step.

This would give the model the best possible information at each step. We can evaluate our machine learning model on the most recent data available at each step.

## Your Start in Machine Learning

You can master applied Machine Learning without math or fancy degrees.

Find out how in this *free* and *practical* course.

Email Address

[START MY EMAIL COURSE](#)

There are few decisions to make:

1. **Minimum Number of Observations.** First, we must select the minimum number of observations required to train the model. This may be thought of as the window width if a sliding window is used (see next point).
2. **Sliding or Expanding Window.** Next, we need to decide whether the model will be trained on all data it has available or only on the most recent observations. This determines whether a sliding or expanding window will be used.

After a sensible configuration is chosen for your test-setup, models can be trained and evaluated.

1. Starting at the beginning of the time series, the minimum number of samples in the window is used to train a model.
2. The model makes a prediction for the next time step.
3. The prediction is stored or evaluated against the known value.
4. The window is expanded to include the known value and the process is repeated (go to step 1.)

Because this methodology involves moving along the time series one-time step at a time, it is often called Walk Forward Testing or Walk Forward Validation. Additionally, because a sliding or expanding window is used to train a model, this method is also referred to as Rolling Window Analysis or a Rolling Forecast.

This capability is currently not available in scikit-learn, although you could contrive the same effect with a carefully configured `TimeSeriesSplit`.

Below is an example of how to split the data into training and validation sets using the `TimeSeriesSplit` Validation method.

```
1 from pandas import Series
2 from matplotlib import pyplot
3 series = Series.from_csv('sunspots.csv')
4 X = series.values
5 n_train = 500
6 n_records = len(X)
7 for i in range(n_train, n_records):
8     train, test = X[0:i], X[i]
9     print('train=%d, test=%d' % (len(train), len(test)))
```

## Your Start in Machine Learning

You can master applied Machine Learning without math or fancy degrees.

Find out how in this *free* and *practical* course.

START MY EMAIL COURSE

Running the example simply prints the size of the training and test sets created. We can see the train set expanding each time step and the test set fixed at one time step ahead.

Within the loop is where you would train and evaluate your model.

```
1 train=500, test=1
2 train=501, test=1
3 train=502, test=1
4 train=503, test=1
5 train=504, test=1
6 ...
7 train=2815, test=1
8 train=2816, test=1
9 train=2817, test=1
10 train=2818, test=1
11 train=2819, test=1
```

You can see that many more models are created.

This has the benefit again of providing a much more robust estimation of how the chosen modeling method and parameters will perform in practice. This improved estimate comes at the computational cost of creating so many models.

This is not expensive if the modeling method is simple or dataset is small (as in this example), but could be an issue at scale. In the above case, 2,820 models would be created and evaluated.

As such, careful attention needs to be paid to the window width and window type.

These could be adjusted to contrive a less computationally expensive.

Walk-forward validation is the gold standard validation of the time series world.

# Summary

In this tutorial, you discovered how to backtest machine learning models on time series data with Python.

Specifically, you learned:

- About the importance of evaluating the performance of models on unseen or out-of-sample data.
- How to create train-test splits of time series data, and how to create multiple such splits automatically.
- How to use walk-forward validation to provide the most realistic test harness for evaluating your models.

Do you have any questions about evaluating your time series model or about this tutorial?

Ask your questions in the comments below and I will do my best to answer.

Hi Shreyak,

Yes, that would be a sampled version of walk-forward validation, a subset.

This is pretty much what the multiple train-test splits provides in the sklearn TimeSeriesSplit object – if I understood you correctly.

**Kingsley Udeh** January 27, 2019 at 4:28 am #

REPLY ↗

Hi Dr. Jason,

Based on Shreyak's idea of simplifying WVF, it requires you to have a common h-steps factor for total observations and minimum train samples , respectively, evenly dividing both quantities. Therefore expanding the window width by the common factor, and at same time, keeping h steps for prediction consistent at each iteration.

However, the limitation with this approach is if the common factor is 1 or even 2, or 3, and you have a large train samples, it would still default back to the traditional WVF, which is time consuming. This is where TimeSeriesSplit object comes in – that is, having a reasonable set of splits that is relevant even with large train samples.

In conclusion, it's possible to combine multiple train-test splits method and WVF technique by expanding each train split and retraining the model, while maintaining a consistent test split.

Dr. Jason, what's your take?

**Jason Brown**

My take is that I stick to simple walk fo

My query is related to walk forward validation:

Suppose a time series forecasting model is trained with a set of data and gives a good evaluation with test-set in time\_range-1 and model produces a function F1. For time\_range-2 and another set of training and testing data model generates function F2. Similarly for time\_range-N the model generate Function FN. How the different models when combined and implemented forecast the result based on forecasting function based of local model and not the combined model of all time range model, which may possibly be producing error in forecasting.

Hi Jason

Thanks so much for this in-depth post. My question is:

Which performance measure should we use in selecting the model?

For example, if I add one test subset at a time in a binary(1, 0) classification problem, the accuracy would be either 1 or 0.

In this case, how should I select a model? Should I use other measures instead?

I am building my model as stock price classification where 1 represents up, and 0 means down. I use TimeSeriesSplit and divide into T (sample size) – m (rolling window) + 1.

Thanks a lot and I look forward to listening your insights!

Hi Ian,

Walk forward validation is a method for estimating the skill of the model on out of sample data. We contrive out of sample and each time step one out of sample observation becomes in-sample.

We can use the same model in ops, as long as the walk-forward is performed each time a new observation is received.

Does that make sense?

**Magnus** March 4, 2017 at 2:39 am #

REPLY ↗

Thanks Jason for an informative post!

If the time series is very long, e.g. minute values for 10 years, it will take a very long time to train. As I understand you, another way to do this is to fix the length of the training set, e.g. 2 years, but just move it, like this:

Split 1: year 1+2 train, year 3 test

Split 2: year 2+3 train, year 4 test

...

Split 8: year 8+9 train, year 10 test

Is this correct and valid?

**Jason Brownlee** Ma

Sounds good to me.

Thank you for your post J

I would like to ask you which model  
In fact, for example if the time series  
applied in this way:

Split 1: year 1 train, year 2 test and

Split 2: year 1+2 train, year 3 test a

which model should we then choose ?

**Jason Brownlee** May 11, 2017 at 8:32 am #

REPLY ↗

Great question.

Pick the model that best represents the performance/capability required for your application.

**Elie Kawerk** June 24, 2017 at 8:14 pm #

REPLY ↗

Jason,

I think that when Marwa mentioned ‘models’, she meant applying the same model (such as ARMA) on different data (corresponding to the expanding window).

I think that the walk-forward method, just like k-fold CV, gives an array of metrics whose mean somehow corresponds to the true skill of the model.

I think that when this mean is evaluated, the model should be trained on the entire dataset (check Practical Time Series Forecasting with R- Shmueli ) just like with K-fold CV.

Please correct me if I am wrong.

Regards

**Jason Browne**

Dear Jason,

Thanks so much for this in-depth post. My question is:

If my time series are discontinuous(such as two weeks in March and two weeks in September), How should I divide the data set?

If I use time series as supervised learning, it could lead to a sample containing data for March and September.

This question has puzzled me for a long time and I look forward to hearing from you.

REPLY ↗

I don't have a good answer.

Perhaps try to fill in the missing time with 0s or nans.

Perhaps try to ignore the missing blocks.

Perhaps focus on building a model at a lower scale (month-wise).

**Nick** July 7, 2017 at 12:57 pm

Hey Jason, can you comment on how this fact, be used for time-series data (

You would have to fit the model on just the new data or on a combination of the new and old data.

This can be done with a new model or by updating the existing model.

I do not have an example with ARIMA, but I do have examples with LSTMs here:

Hi, Jason

Thanks a lot for this post, I have recently gone through many of your blog posts on time series forecasting and found it quite informative; especially the post on feature engineering for time series so it can be tackled with supervised learning algorithms.

Now, if I have a time series data for demand forecasting, and I have used a lot of feature engineering on the 'date' variable to extract all the seasonality, for example, day, month, the day of the week, if that day was a holiday, quarter, season, etc. I have also used some FE on the target variable to create lag features, min, max, range, average, etc.

My question to you is: Do I still need to now use a simple k-fold cross validation? Is it important?

Thanks a lot. Keep doing this awesome work!

Huzefa

Hi Jason,

Thank you so much for this post.

However I will have a question that might seems stupid but...

This give me a graphical version of the reality (on the train) and of my predictions (on the test). But it is not an evaluation of my model....

How do I know using those methods, if my models is great or bad?

Imagine I want to try an ARIMA (5,2) and an ARIMA (6,3). How do I do to pick the best one? How do I evaluate each one using "Walk Forward Validation"????

To evaluate the first model, I can do the mean of the error, for each split, between the prediction and the real value?

To pick the best model I can compare those mean between the 2 models?

Would it be a good evaluation methods?

Thank you again!

**Jason Brownlee** November 5, 2017 at 5:15 am #

REPLY ↗

You can compare the predictions to the expected values and calculate an error score.

Here are some examples:

**Urfa** January 22, 2018 at 10:38

Hi Jason,

I have a set of monthly panel data values. In detail, I want to predict regression with a fixed window size

panel data like regression with fixed effects, but in my case, with pooled OLS I'm getting accurate predictions.) Regression model looks like this:  $y_{\{i,t+1\}} = b_0 + b_1 * x_{\{i,t\}} + b_2 * x_{\{i,t\}} + \dots + x_{10,\{i,t\}}$  where t is the current month and i is the id.

Furthermore, I select a new model in every step by using a dynamic model selection. In detail:

1. Take a fixed windows size of five years and split it into a training and validation set. The first 58 months as training and the month 59 as validation set.
2. Choose Explanatory Variables or rather a regression model by running a stepwise regression for model selection with the training and validation set and the Average Square Error of the validation set as a criterion.
3. Take the data from month 60 and the regression model from step 2, to make a forecast for month 61.
4. Go to step 1 and roll the window one month forward.

I couldn't find any literature where you select a new regression model or new explanatory variables at every step of the rolling regression. Do you know if there is any literature on that?

Thank you!

Hang in there.

Generally, there is no one size fits all approach. Often you need to dive in and try stuff and see what suits the problem/data/project.

**Mohammed Helal** February 6, 2018 at 5:57 am #

REPLY ↗

Correct me if I'm wrong, but it seems to me that TimeSeriesSplit is very similar to the Forward Validation technique, with the exceptions that (1) there is no option for minimum sample size (or a sliding window necessarily), and (2) the predictions are done for a larger horizon.

PS. Thanks a lot for your posts!

**Jason Brownlee** February 6, 2018 at 9:23 am #

REPLY ↗

It is a one-time split, whereas walk-forward validation splits on each time step from one point until the end of the dataset.

Does that help?

**Alexis** March 2, 2018 at 5:14 pm #

Hi Jason, I don't see why to create a test set of constant size window at the first iteration, and then be correct ?

REPLY ↗

**Tarun** March 15, 2018 at 10:31 pm #

Hi Jason,

I have a query regarding Walk forward validation of TS. Let's say I need to forecast for next 3 months (Jan-Mar 18) using last 5 years of data (Jan13-Dec 17).

In principle I would want to use Walk forward as I would like to see how well the model generalizes to unseen data. I'd use your approach which is:

- 1) Set Min no of observations : Jan12-Dec 16
- 2) Expanding TEST window : Entire 2017, which means I would forecast next 3 points (Jan-Mar 17) in iteration 1 and in next iteration, Jan 17 becomes part of train and I predict for Feb-mar-April 17.I do it for entire 2017.

My question is why do I need to RETRAIN model everytime I add 1 data point? Why can't I just score the next 3 TEST points assuming the fact that model that I have trained before ITR1 is the best one?

Can't I select (let's say) top 5 models from step 1,calculate their Average for all TEST samples (3 months window) and select the one with least RMSE?.

Eagerly awaiting your reply!

**Jason Brownlee** Ma

You can, but the further skill will be come.

That sounds like a great problem.

I'm eager to dive in and offer some advice, but it would be a big time investment for me, I just don't have the capacity. I hope to have more posts on this topic soon.

In general, I recommend testing a suite of modeling methods and framings of a problem to help you discover what works best for your specific dataset.

I'm eager to hear how you go.

**Dicky Chou** April 23, 2018 ↗

REPLY ↗

Hi Jason

I am a meteorologist currently working at the University of California, Berkeley. My colleagues make forecasts every day, and I find that there are some time shifts between our forecasts. For example, we think it will be raining at 4 PM, but it actually starts at 6 PM. If we use normal verification measures, such as false alarm rate, we will get a high false alarm. However, I think this error is due to the weather condition at 4 PM, not the forecast. Can you help me understand the attribution of these data? Can you provide any resources for learning time series data?

Dear Dr Jason,

For those having difficulty plotting the data sourced from the site  
<https://datamarket.com/data/set/22ti/zuerich-monthly-sunspot-numbers-1749-1983> ,  
The following may be helpful before even using Python.

Even if you imported the file from the website as a CSV file, the trouble is that there are NaN values and extraneous information at the bottom of the spreadsheet. It requires cleaning the file. Otherwise if the file is not cleaned, Python will produce error messages.

- (1) Open the sunspot.csv file into a spreadsheet program eg MS Excel
- (2) Leave the header at the top of the file alone.
- (3) Scroll down to the very end of the data file (2821 rows down). Delete the rows containing Nan and text “Zuerich monthly sunspot numbers 1749-1983”.
- (4) Save the file as sunspot.csv in CSV format
- (3) In Python import the data as usual

```
1 Series.read_csv('sunspot.csv', header=0)
```

Everything should be OK from that point.

Thank you,  
Anthony of Sydney

Hi Jason,

Thanks as always.

Please how do I train and evaluate my model within the loop of a Walk Forward Validation approach?

Within the Walk Forward Validation, after choosing my min training size, I created, say for, eg.

range of train to len(records):

```
train, test = X_obs[0:i], X_obs[i:i+1]
```

```
# Fit Model
```

```
history = model.fit(train_X, train_y, epochs=1000, batch_size=4192, validation_data=(test_X, test_y), verbose=0, shuffle=False)
```

```
# Evaluate Model
```

```
loss = model.evaluate(test_X, test_y, verbose=0)
```

```
print(loss)
```

```
model.save('lstm_model.h5')
```

At the end, I have 10 different loss or validation scores. Is the last saved model the average of all the 10 models? How do I make predictions and calculate the RMSE for the average model?

I'm still learning the Walk Forward Validation method and will appreciate your help in guiding me on the right thing to do

I look forward to hearing from you

Jason Brownlee July 12, 2018 at 7:40 pm #

I recommend not using the mean score as it is calculated based on the validation loop.

**Philip P** August 18, 2018 at 12:55 am #

REPLY ↗

Jason,

So, I'm wondering how these folds from Walk Forward Validation would be passed into a python pipeline or as a CV object into a sklearn model like xgboost. I've used GridSearchCV to create the cross-validation folds before. My project at work has sales data for a number of stores each week. I'm creating a model that will predict sales 4 weeks out by each store. Right now, I have a max of 80 weeks of data. I figured to start with a minimum train size of 52 weeks and test on the next 4 weeks. Each fold would jump 4 weeks ahead. Here, n\_train = 52 and max\_week = 80. My code and output are below. Thanks so much!

Code:

```
for i in range(n_train, max_week):  
    if i % 4 == 0:  
        train, test = df[(df.WeekCount_ID >  
        4)]  
        print('train=%d, test=%d' % (len(ti
```

Output:

```
train=3155, test=260  
train=3415, test=260  
train=3675, test=260  
train=3935, test=260
```

Coming to my question,  
how to use ML binary classification concepts in case of nonstationary data (Example:  
EEG data)?

At present, with the help of available samples, I train the model using KV fold cross-validation.

```
clf=ML-Classifcationmodel();  
y_pred = cross_val_predict(clf,MyX,MyY,cv=10)
```

every time I am getting the same results.

but if I shuffle the samples before training using below syntax, every time I am getting different results.

```
from sklearn.utils import shuffle  
mydataset = shuffle(df1)
```

how to find the best model in such cases.

**Jason Brownlee** October 1, 2018 at 6:25 am #

REPLY ↗

It's not valid to use cross validation for time series data, regression or classification.

The train/test data must be split in such a way as to respect the temporal ordering and the model is never trained on data from the future and only tested on data from the future.

**Will** November 13, 2018

There has been a paper that if your problem is a pure framing of an ML problem it is valid to use K-Fold cross validation. The results produced by the model are

The paper can be found here:

One question:

I want to know what window-size is best for my project.

Imagine your dataset has 2000 rows. If I use a window size of 1000, I get a RMSE of 1500. If I use a window size of 500, I get a RMSE of 1000. If I use a window size of 250, I get a RMSE of 800.

Later in that loop my windows size is reduced to 100, which is still fitting and I only get 800 RMSE results.

Is it fair to compare the performance of these models?

Or would it be better to ensure a stable error over time?

REPLY ↗

Excellent question.

I recommend testing a suite of window sizes in order to discover the effect it has on your model for your specific dataset.

Bigger is not always better.

**Andre** December 3, 2018 at 12:13 pm #

REPLY ↗

Sorry for my reply but i think i didn't get the point ;).

A better example: A data set with 10000 rows, we want to know which window size performs best. For fast execution we only use the last N Values to run some tests...

TEST A) First we use the last 2000 data points to test different window sizes (200,300,400). We start our first run with win-size 200, we train on 1:200 and check performance on 201:201+horizon. We collect RMSE values for each “fold & horizon” and go further, step by step (+1) until we reach index >20004000 The smaller the window size (200), the more data i have less data to test.

Do i have to use a “fixed” test area thumb here?

That's really confusing me, many t

Thank you Jason for your work.

When you work with a neural network with a sliding window, you make a new training at each step. Would it make sense to start the new step with the neural networks weights obtained in the previous one as big part of the training samples can be the same?

If so, how would you do it in Python?

Best Regards.

**Jason Brownlee** April 17, 2019 at 6:57 am #

Hi Jason,

Thank you for this great tutorial.

What do you think about doing the multiple train-test splits in a different way:

You split the data at a certain point to a trainset and a testset.

Then you use bootstrap or a “semi” k-fold cross validation where you randomly split both the train and test sets into k folds and then train the model k times, each time on k-1 folds of the trainset and evaluate the model on k-1 folds of the testset.

What are the advantages of using the multiple train-test splits that you proposed above over this approach?

Thanks!!

Anat

BobIsYourUncle May 10, 2019 at 10:30 pm #

If my model does not use features that incorporate information about prior samples, then how does a k-fold “cheat”? It seems like if the data in any fold is likely to repeat in the future, then why is the test result from fold 1 (thus training occurs on folds 2 thru 10) in a 10 fold CV invalid? I can see how re-sampling before k-fold CV is problematic (i.e. removing the data’s temporality), but have a hard time understanding the assertion that k-fold cannot be applied to time series data – full stop. Is your assertion always true, or is it model/feature dependent? I apologise for inquiring about something that should probably be obvious. Your website is awesome and your pedagogy’s on point. Thanks for all the help.

**Jason Brownlee** May 10, 2019 at 1:39 pm #

REPLY ↗

The ordering of observations by time can cause a problem, as the model may have access to a future it may be asked to predict.

Does that help?

**BobIsYourUncle** May 11, 2019 at 4:49 am #

REPLY ↗

I can wrap my head around it at a high level and never consider using k-fold for my time-series dataset/feature/model configurations. That said, as I fall further down the ML rabbit hole, I find certain configurations that make me question the assertion. Questioning it will undoubtedly come at a cost if I don’t make an effort to rigorously

Can you recommend any k-fold temporal/nontemporal datasets?

**BobIsYourUncle** May 11, 2019 at 10:29 am #

REPLY ↗

I think I have a very fundamental misunderstanding of data types. While some data I have is sampled temporally, previous samples do not inform the outcome of future examples. That is, I currently consider data to be “time series” data even though no autocorrelation exist. If a set of time series data exhibits no autocorrelation, is it still considered flawed in a k-fold CV. I wish we had a whiteboard between us so you could explain this to me in 10 secs.

**Jason Brownlee** May 12, 2019 at 6:37 am #

REPLY ↗

If the data is sequential (e.g. ordered by time), k-fold cross validation is probably a bad idea.

Hello Jason,

It amazes me after reading dozens of your blogs about time series. It still remains some confusions.

In my case, I try to use LSTM for univariate forecast.

1. I have read your post "How to C Problem in Python" before, and train learning. If I want to apply backtesting, what's the transformed sequence?

2. In "Multiple Train-Test Splits" section, it says "use a case(case with as much data as possible)

3. It seems ambiguous when combining "forward validation". According to me, we should use supervised-learning data first, then training data.

The shortest path to understanding is here:

[https://machinelearningmastery.com/start-here/#deep\\_learning\\_time\\_series](https://machinelearningmastery.com/start-here/#deep_learning_time_series)

Or my book.

Or a complete tutorial, like this one:

<https://machinelearningmastery.com/how-to-develop-deep-learning-models-for-univariate-time-series-forecasting/>

Nevertheless:

1. Backtesting is performed on the transformed data, e.g. transform the data to a supervised learning problem after scaling/differencing/etc.
2. The idea is to estimate the performance of the model when making predictions on new data and determine if it has skill by comparing performance to a baseline model. Your chosen algorithm may or may not perform better with more history.
3. You can choose to update the model after every step forward or not. I often do not as its to computationally expensive..

Finally, LSTMs are terrible at univariate time series forecasting:

<https://machinelearningmastery.com/findings-comparing-classical-and-machine-learning-methods-for-time-series-forecasting/>

Use an SARIMA or ETS instead
